

(a) What the test can see

(b) What is actually there

(c) Why no band can be named

The cohort separates on standing ability, not on learning rate. At the block length actually administered the learning-rate axis carries so little information that the fitted admission boundary weights it 0.33 $\times$ standing (solid line, panel a); a 60-trial block would raise that to 0.69 $\times$ (dashed). Panel (c) is why: the readout's total uncertainty is 0.145 wide, nearly five times the 0.03-wide band it would have to sit inside, so no learning rate is reportable at all today.
